**Abstract.** The distribution of overlaps of solutions of a random CSP is an indicator of the overall geometry of its solution space. For random  $k$ -SAT, nonrigorous methods from Statistical Physics support the validity of the “one step replica symmetry breaking” approach. Some of these predictions were rigorously confirmed in [MMZ05a] [MMZ05b]. There it is proved that the overlap distribution of random  $k$ -SAT,  $k \geq 9$ , has discontinuous support. Furthermore, Achlioptas and Ricci-Tersenghi [ART06] proved that, for random  $k$ -SAT,  $k \geq 8$ , and constraint densities close enough to the phase transition:

- there exists an exponential number of clusters of satisfying assignments.
- the distance between satisfying assignments in different clusters is linear.

We aim to understand the structural properties of random CSP that lead to solution clustering. To this end, we prove two results on the cluster structure of solutions for binary CSP under the random model from [Mol02]:

1. For all constraint sets  $S$  (described in [CD04,Ist05]) s.t.  $SAT(S)$  has a sharp threshold and all  $q \in (0, 1]$ ,  $q$ -overlap- $SAT(S)$  has a sharp threshold (i.e. the first step of the approach in [MMZ05a] works in all nontrivial cases).
2. For any constraint density value  $c < 1$ , the set of solutions of a random instance of 2-SAT form, w.h.p., a single cluster. Also, for and any  $q \in (0, 1]$  such an instance has w.h.p. two satisfying assignment of overlap  $\sim q$ . Thus, as expected from Statistical Physics predictions, the second step of the approach in [MMZ05a] fails for 2-SAT.

## 1 Introduction

A great deal of insight in the complexity of random constraint satisfaction problems has come from studying *phase transitions* [MZ97]. Concepts from Statistical Physics, such as *first-order phase transitions*, *backbones*, or *replica symmetry breaking* have helped to refine (and understand the limitations of) the empirical observation that the “hardest” instances are located at the transition point. In some cases the connection predicted by Statistical Physics can be made explicit in purely combinatorial terms. For instance Monasson et al. [MZK<sup>+</sup>99b,MZK<sup>+</sup>99a] have suggested that *first-order phase transitions* are correlated with exponential complexity of Davis-Putnam algorithms on random *unsatisfiable* instances at the phase transition. This has been rigorously confirmed to a certain extent [AKKK01,ABM04,IPB05]. As for instances in the satisfiable phase, much of the intuition on the complexity of such instances comes again from Statistical Physics, via the so-called *one step replica symmetry breaking* (1-RSB) approach. The 1-RSB approach provides predictions on the geometric structure of the set

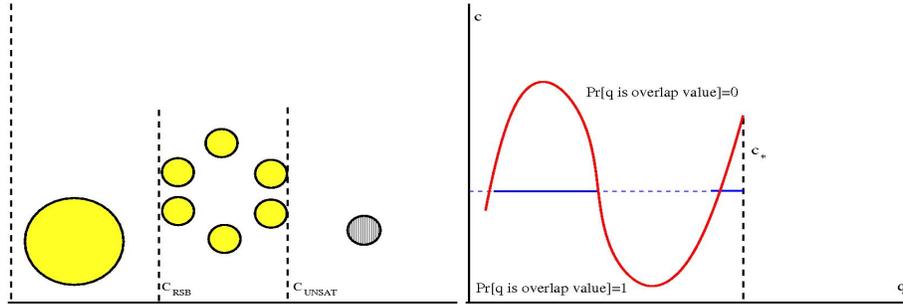

of satisfying assignments of a random formula on  $n$  variables. The set of such assignments can be naturally viewed as a subgraph of the *hypercube of dimension  $n$* , where two satisfying assignments are *neighbors* if they only differ in the value of one variable. Physics considerations imply that for small values of the constraint density  $c$  the set of satisfying assignments forms a single cluster. The distribution of overlaps is peaked around a certain constant value. The range of possible overlaps (even those that are exponentially infrequent) is a continuous interval. In the presence of 1-RSB, for constraint density values higher than a critical value  $c_{RSB}$  (smaller than the unsatisfiability threshold  $c_{UNSAT}$ ) the set of satisfying assignments splits into several *clusters* such that: (i) assignments in the same cluster all agree on a set of variables having linear size. The distribution of overlaps of assignments in the same cluster is still concentrated around a constant; (ii) assignments in different clusters differ in  $\Omega(n)$  variables; (iii) the distribution of all overlaps has discontinuous support (see Fig. 1 (a); note that recent studies [KMRSZ07] suggest the existence of further phases below  $c_{RSB}$ , omitted for simplicity from discussion and the figure). The geometry of satisfying assignments outlined above has implications for the complexity of heuristics such as local search, algorithms such as belief propagation, or Davis-Putnam. The 1-RSB approach provides (nonrigorous) values for the location of the phase transition in random  $k$ -SAT [MMZ06] that seems to match the experimental evidence. Algorithms that take advantage of the geometry of solution space predicted by 1-RSB (e.g. the celebrated *survey propagation* algorithm [BMZ05]) have greatly extended the range of instances that can be solved in practice. Rigorous results on the cluster structure of solutions of random CSP are emerging: Mézard et al. [MMZ05a] have developed an ingenious method for proving that the distribution of overlap values of random  $k$ -SAT, with  $k \geq 9$  indeed has discontinuous support. Their approach is based on the following concepts:

**Definition 1.** *The overlap of two assignments  $A$  and  $B$  for a formula  $\Phi$  on  $n$  variables, denoted by  $overlap(A, B)$ , is the fraction of variables on which the two assignments agree (this is similar to [MMZ05a] and linearly related to the notion of overlap from the statistical physics literature, where truth values are modeled by  $+1$  and  $-1$ , instead of  $0/1$ ). Formally  $overlap(A, B) = \frac{|\{i:A(x_i)=B(x_i)\}|}{n}$ .*

The distribution of overlaps is, indeed, the original order parameter that was originally used to study the phase transition in random  $k$ -SAT [MZ97].

**Definition 2.  $q$ -overlap- $k$ -SAT:** *Given a  $k$ -CNF formula  $\Phi$  on  $n$  variables, decide whether  $\Phi$  has two satisfying assignments  $A$  and  $B$  such that  $overlap(A, B) \in [q - 1/\sqrt{n}, q + 1/\sqrt{n}]$  (following the suggestion in [MMZ05a], we will use the function  $1/\sqrt{n}$  for the the width of the possible overlap around  $q$ ; as discussed there, similar results are obtained with any "reasonably large" function  $b(n) = o(n)$ ). We will refer to this event as  $A$  and  $B$  have overlap approximately equal to  $q$ .*

For every value of  $q$ , the probability that a random  $k$ -SAT formula has two assignments with overlap  $\sim q$  is monotonically decreasing with constraint density, and is empirically changing from 1 to 0 around a critical value  $c_{k,q}$  of the constraint density. If one can show that the function  $W : q \rightarrow c_{k,q}$  is *not* monotonic then *there exists a critical value  $c_*$  such that the horizontal line at  $c_*$  will intersect the graph of function*

**Fig. 1.** (a) Structure of solution space according to 1RSB predictions.(b) Graphical description of the method used in [MMZ05a] to prove the discontinuity of support of the overlap distribution.

$W$  at multiple points. Therefore (Figure 1 (b)) the distribution of overlaps in a random  $k$ -SAT formula of constraint density  $c_*$  has discontinuous support (these results were further extended, for  $k$ -SAT,  $k \geq 9$ , by Achlioptas and Ricci-Tersenghi [ART06]).

Our ultimate goal is to obtain an understanding of the underlying reasons for the emergence of clustering in random CSP, with an attempt at a precise classification. We investigate the nature of overlap distributions of CSP under the random model defined and investigated by Molloy [Mol02]. We cannot obtain a complete classification (whether the results in [MMZ05a,ART06] extend to random 3-SAT is a more subtle problem; see [MS07]). Instead, we prove two partial results: Theorem 1 shows that the first step of Mézard’s approach can be applied to all random CSP problems with a sharp threshold. In contrast, in Theorem 2 we show that satisfying assignments of random instances of 2-SAT in the satisfiable phase form a single cluster, and can yield all possible values of the overlap. This confirms the prediction [MZ97] that the solutions space of 2-SAT has a different nature, describes by the so-called “replica symmetric” approach. The two results above are also naturally related to results of Gopalan et al. [GKMP06]. They proved a dichotomy theorem for the complexity of deciding whether the set of satisfying assignments of a CSP is connected (under the usual notion of adjacent assignments). One ingredient of the result is a restriction (called *tightness*) on the nature of constraints involved. Theorem 2 provides a natural examples of CSP with tight constraints for which there is evidence (the continuity of the overlap distribution) that symmetry breaking does not take place. It also shows that, to be really meaningful, the definition of adjacent assignments from [GKMP06] should be somewhat modified.

## 2 Preliminaries

Throughout the paper we will assume familiarity with the general concepts of phase transitions in combinatorial problems (see e.g. [MMZ01]) and random structures. One paper whose concepts and methods we use in detail (and we assume greater familiarity with) is [Fri99]. Consider a monotonically increasing problem  $A = (A_n)$  under the constant probability model  $\Gamma(n, p)$ . For  $\epsilon > 0$  let  $p_\epsilon = p_\epsilon(n)$  define the canonical probability such that  $\Pr_{x \in \Gamma(n, p_\epsilon(n))}[x \in A] = \epsilon$ . The probability that a random sample  $x$

satisfies property  $A$  (i.e.  $x \in A$ ) is a monotonically increasing function of  $p$ . Problem  $A$  has a *sharp threshold* iff for every  $0 < \epsilon < 1/2$ , we have  $\lim_{n \rightarrow \infty} \frac{p_{1-\epsilon}(n) - p_\epsilon(n)}{p_{1/2}(n)} = 0$ .  $A$  has a *coarse threshold* if for some  $\epsilon > 0$  it holds that  $\lim_{n \rightarrow \infty} \frac{p_{1-\epsilon}(n) - p_\epsilon(n)}{p_{1/2}(n)} > 0$ . Related definitions can be given for the other two models for generating random structures, the *counting model* and the *multiset model* [Bol85]. Under reasonable conditions [Bol85] these models are equivalent, and we will liberally switch between them. In particular, for satisfiability problem  $A$ , and an instance  $\Phi$  of  $A$ ,  $c_A(\Phi)$  will denote its *constraint density*, the ratio between the number of clauses and the number of variables of  $\Phi$ . To specify the random model in this latter cases we have to specify the constraint density as a function of  $n$ , the number of variables. We will use  $c_A$  to denote the value of the constraint density  $c_A(\Phi)$  (in the counting/multiset models) corresponding to taking  $p = p_{1/2}$  in the constant probability model.  $c_A$  is a function on  $n$  that is believed to tend to a constant as  $n \rightarrow \infty$ . However, Friedgut's proof [Fri99] of a sharp threshold in  $k$ -SAT (and our results) leave this issue open.

**Definition 3.** Let  $\mathcal{D} = \{0, 1, \dots, t-1\}$ ,  $t \geq 2$  be a fixed set. Consider the set of all  $2^k - 1$  potential nonempty binary constraints on  $k$  variables  $X_1, \dots, X_k$ . We fix a set of constraints  $\mathcal{C}$  and define the random model  $\text{CSP}(\mathcal{C})$ . A random formula from  $\text{CSP}_{n,p}(\mathcal{C})$  is specified by the following procedure: (i)  $n$  is the number of variables; (ii) for each  $k$ -tuple of ordered distinct variables  $(x_1, \dots, x_k)$  and each  $C \in \mathcal{C}$  add constraint  $C(x_1, \dots, x_k)$  independently with probability  $p$ . We will write  $\text{SAT}(\mathcal{C})$  instead of  $\text{CSP}(\mathcal{C})$  for boolean constraint satisfaction problems (i.e.  $t = 2$ ).

**Definition 4.** Let  $\mathcal{D} = \{0, 1, \dots, t-1\}$ ,  $t \geq 2$  be a fixed set. Let  $q$  be a real number in the range  $[0, 1]$ . The problem  $q$ -overlap-CSP( $\mathcal{C}$ ) is the decision problem specified as follows: (i) The input is an instance  $\Phi$  of  $\text{CSP}_{n,p}(\mathcal{C})$ ; (ii) The decision problem is whether  $\Phi$  has two satisfying assignments  $A, B$  such that  $\text{overlap}(A, B) \in [q - 1/\sqrt{n}, q + 1/\sqrt{n}]$  (following [MMZ05b], we will informally refer to the property as “ $\Phi$  is  $q$ -satisfiable”). The random model for  $q$ -overlap-CSP( $\mathcal{C}$ ) is simply the one for  $\text{CSP}_{n,p}(\mathcal{C})$ . We will refer to this class of problems as fixed-overlap CSP.

The notion of adjacent satisfying assignments used in [ART06], while adequate for random  $k$ -SAT, is not suited for other random CSP. For instance, it is impossible to flip exactly one bit in a satisfying assignment of an instance of 1-in- $k$  SAT [ACIM01] and still obtain a satisfying assignment (except for the case when that variable does not appear in the formula). Thus we will use the following setup: let  $f(n) = o(n)$  be a suitably large function; we will assume that  $\lim f(n)/\log n = \infty$ . Two satisfying assignments that differ on at most  $f(n)$  variables will be called adjacent. A *cluster* is a connected component of the set of satisfying assignments.

### 3 Results

In this section we study the sharpness of the threshold for random generalized constraint satisfaction problem defined by Molloy [Mol02]. Creignou and Daudé [CD04] (and independently the author of this paper [Ist05]) have characterized the boolean CSP problems  $\text{SAT}(\mathcal{C})$  with a sharp threshold:

**Definition 5.** A set of constraints  $\mathcal{C}$  is interesting if there exist constraints  $C_0, C_1 \in \mathcal{C}$  with  $C_0(\bar{0}) = C_1(\bar{1}) = 0$ , where  $\bar{0}, \bar{1}$  are the "all zeros" ("all ones") assignments. Constraint  $C_2$  is an implicate of  $C_1$  iff every satisfying assignment for  $C_1$  satisfies  $C_2$ . A boolean constraint  $C$  strongly depends on a literal if it has an unit clause as an implicate. A boolean constraint  $C$  strongly depends on a 2-XOR relation if  $\exists i, j \in \{1, \dots, k\}$  such that constraint " $x_i \neq x_j$ " is an implicate of  $C$ .

**Proposition 1.** [CD04,Ist05] Consider a generalized satisfiability problem  $SAT(\mathcal{C})$  with  $\mathcal{C}$  interesting. (i) If some constraint in  $\mathcal{C}$  strongly depends on one literal then  $SAT(\mathcal{C})$  has a coarse threshold; (ii) If some constraint in  $\mathcal{C}$  strongly depends on a 2XOR-relation then  $SAT(\mathcal{C})$  has a coarse threshold; (iii) In all other cases  $SAT(\mathcal{C})$  has a sharp threshold.

Mora et. al [MMZ05b] proved that all problems  $q$ -overlap- $k$ -SAT,  $k \geq 2$  have a sharp threshold. We extend this result by showing that for all CSP with a sharp threshold, their fixed-overlap versions also have a sharp threshold:

**Theorem 1.** Consider a generalized satisfiability problem  $SAT(\mathcal{C})$  such that (i)  $\mathcal{C}$  is interesting (ii) No constraint in  $\mathcal{C}$  strongly depends on a literal; (iii) No constraint in  $\mathcal{C}$  strongly depends on a 2XOR-relation. Then for all values  $q \in (0, 1]$  the problem  $q$ -overlap- $SAT(\mathcal{C})$  has a sharp threshold.

The previous result does not yet rigorously prove the existence of curve  $W$  since it does not prove fact that the phase transition in the  $q$ -overlap versions happens at some constant constraint density  $c_q$ .

Given the previous result, how can a problem  $SAT(\mathcal{C})$  have an overlap distribution with continuous support? Obviously, the second step of the approach in [MMZ05a] must fail. This happens when the location  $c_q$  of the transition for the  $q$ -overlap version of  $SAT(\mathcal{C})$  is a monotonic function of the overlap  $q$ . The next result shows gives a natural problem for which this is indeed the case:

**Theorem 2.** The following are true:

- (i) Let  $c < 1$ . Then with probability  $1 - o(1)$  the satisfying assignments of a random instance of 2-SAT of constraint density  $c$  form a single cluster.
- (ii) Also, let  $q \in (0, 1]$ . Let  $c < 1$ . Then with probability  $1 - o(1)$  a random instance of 2-SAT of constraint density  $c$  is  $q$ -satisfiable.

## 4 Proof of Theorem 1

Before presenting the proof, let us remark that for boolean constraints, the hypothesis of the Theorem 1 implies that the set of constraints  $\mathcal{C}$  is *well-behaved*. That is [Mol02], every formula whose hypergraph is tree-like or unicyclic is satisfiable. This is, for instance, an easy consequence of conditions (D0),(D1), Theorem 4.1 in [CD04]. Also, since  $\mathcal{C}$  is interesting there exist constraints  $\Gamma_0, \Gamma_1 \in \mathcal{C}$  such that  $\Gamma_0(x_1, \dots, x_k) \models \bar{x}_1 \vee \dots \vee \bar{x}_k$  and  $\Gamma_1(x_1, \dots, x_k) \models x_1 \vee \dots \vee x_k$ .

We will employ the Friedgut-Bourgain criterion for the existence of a sharp threshold of a monotonic property  $A$ . Note that any problem  $q$ -overlap-SAT( $\mathcal{C}$ ) is indeed monotone, since adding clauses can only reduce the set of satisfying assignments, in particular decreasing the probability of  $q$ -satisfiability. The starting point of all applications of the Friedgut-Bourgain criterion is noting that if a monotone property  $A$  has a coarse threshold then there exists  $0 < \epsilon < 1/2$ ,  $p^* = p^*(n) \in [p_{1-\epsilon}, p_\epsilon]$  and  $C > 0$  such that  $p \cdot \frac{d\mu_p(A)}{dp} \Big|_{p=p^*(n)} < C$ . Bourgain and Friedgut have shown that the following holds:

**Proposition 2.** *Suppose  $p = o(1)$  is such that  $p \cdot \frac{d\mu_p(A)}{dp} \Big|_{p=p^*(n)} < C$ . Then there is  $\delta = \delta(C) > 0$  such that either  $\mu_p(x \in \{0, 1\}^n \mid x \text{ contains } x' \in A \text{ of size } |x'| \leq 10C) > \delta$ , or there exists  $x' \notin A$  of size  $|x'| \leq 10C$  such that  $\mu_p(x \in A \mid x \supset x') > \mu_p(A) + \delta$ .*

(in fact, in [Fri99] the proposition is stated assuming for convenience that  $p = p_{1/2}$ , but this is not needed. We give here the general statement). We will need, in fact, an enhancement to the Bourgain-Friedgut result that was given by Friedgut in [Fri05]: For a finite set of words  $W$  define *the filter generated by  $W$* ,  $F(W)$  as  $F(W) = \{x \mid (\exists y \in W) \text{ with } x \supseteq y\}$ . Friedgut noted ([Fri05], remarks on pages 5-6 of that paper) that the set  $W$  of “booster” sets  $x'$  in the second conditions satisfies  $\mu_p(F(W)) = \Omega(1)$ .

Consider now a set of constraints  $\mathcal{C}$  satisfying the conditions the Theorem, and let  $A = q\text{-overlap-SAT}(\mathcal{C})$ . Applying Proposition 2 enhanced by the previous observation, and taking into account the fact that the number of isomorphism types of formulas of size at most  $10C$  is finite, we infer that we can assume that formula  $x'$  in the second condition appears with probability  $\Omega(1)$  as a subformula in a random formula in  $q\text{-overlap-SAT}_p(\mathcal{C})$ . Furthermore, instead on conditioning on the presence of  $x'$  as a subset of  $x$  one can, instead, add it. Finally, note that for random constraint satisfaction problems, because of the invariance of such problems under variable renaming, one only needs to add a random copy of  $x'$ . Putting all these observations together, the following version of Proposition 2 holds:

**Proposition 3.** *Suppose  $p = o(1)$  is such that  $p \cdot \frac{d\mu_p(A)}{dp} \Big|_{p=p^*(n)} < C$ . Then there is  $\delta = \delta(C) > 0$  such that either*

$$\mu_p(x \in \{0, 1\}^n \mid x \text{ contains } x' \in A \text{ of size } |x'| \leq 10C) > \delta \quad (1)$$

*or there exists  $F \notin A$  of size  $|F| \leq 10C$ , such that*

- *Formula  $F$  appears with probability  $\Omega(1)$  as a subformula in a random formula in  $CSP_p(\mathcal{C})$ .*
- *If  $\Xi$  denotes the formula obtained by creating a copy of  $x'$  on a random set of variables, then*

$$\mu_p(x \cup \Xi \in A) > \mu_p(A) + \delta. \quad (2)$$

To show that random  $q$ -overlap-SAT( $\mathcal{C}$ ) has a sharp threshold, we will reason by contradiction. Assuming this is not the case, one needs to prove that the two conditions in Proposition 3 do not hold.

Suppose, indeed, that condition (1) was true. That is, with positive probability it is true that a random formula  $\Phi \in CSP(\mathcal{C})$  contains some subformula  $\Phi' \in \overline{q\text{-overlap-SAT}(\mathcal{C})}$  of size at most  $10C$ . With high probability all subformulas of a random formula  $\Phi$  of size at most  $10C$  are either tree-like or unicyclic. But because the set of constraints  $\mathcal{C}$  is well-behaved (this is the point where the hypothesis on the constraint set  $\mathcal{C}$  is used), all formulas in  $CSP(\mathcal{C})$  that are tree-like or unicyclic are satisfiable. Since the formula contains a finite number of variables, one can set the other variables not appearing in  $\Phi$  in a way that will create two satisfying assignments with overlap approximately  $q$ . Therefore the first condition in Proposition 3 cannot be true.

Assume, now, that condition (2) is true. That is, there exists  $F \in q\text{-overlap-SAT}(\mathcal{C})$ , a formula of size at most  $10C$ , such that adding  $F$  to a random formula  $\Phi \in CSP_p(\mathcal{C})$  diminishes the probability that the resulting formula has two assignments of overlap  $\simeq q$  by at least a constant  $\delta$ . As discussed, we assume that  $F$  occurs with probability  $\Omega(1)$  in a random formula in  $CSP_p(\mathcal{C})$ . Therefore  $F$  is tree-like or unicyclic.

**Definition 6.** A unit clause is a constraint (not necessarily part of the constraint set  $\mathcal{C}$ ) specified by a condition  $X = \delta$ , with  $X$  being a variable and  $\delta \in \{0, 1\}$ .

**Lemma 1.** If  $F$  satisfies condition (2) then there exists another formula  $G$  that is specified by a finite conjunction of unit clauses  $G \equiv (X_1 = \delta_1) \wedge \dots \wedge (X_p = \delta_p)$ , that also satisfies condition (2).

**Proof.** Formula  $F$  appears with constant probability in a random  $CSP(\mathcal{C})$  formula with probability  $p$  and has constant size. Therefore  $F$  is either tree-like or unicyclic. The result follows easily by replacing  $F$  with formula  $G$  consisting of the conjunction of unit constraints corresponding to a satisfying assignment of  $F$ . Indeed,  $G$  is tighter than  $F$ , so adding a random copy of  $G$  instead of a random copy of  $F$  can only increase the probability that the resulting formula is unsatisfiable.  $\square$

The key to refuting condition (2) is to show that, if it did hold then, for every monotonically increasing function  $f(n)$  that tends to infinity, we could also increase the probability of unsatisfiability by a positive constant if, instead of conditioning on  $x$  containing a copy of  $F$ , we add  $f(n)$  random constraints from set  $\mathcal{C}$ . We first prove:

**Lemma 2.** Let  $0 < \tau < 1$  be a constant and let  $p$  be such that  $\mu_p(q\text{-overlap-SAT}(\mathcal{C})) \geq \tau$ . Assume that  $r \geq 1$  and that  $g_1, g_2, \dots, g_r$  are elements of  $\{0, 1\}$  such that, when  $(X_1, X_2, \dots, X_r)$  is a random  $r$ -tuple of different variables

$$Pr(\Phi \text{ has sat. assign. } A, B \text{ of overlap } \simeq q \text{ with } X_1 = g_1, \dots, X_r = g_r) \leq \frac{\tau}{2}. \quad (3)$$

Then there exists constant  $m \geq 1$  (that only depends on  $k, r, \tau$ ) such that, if  $\eta$  denotes a formula from  $CSP(\mathcal{C})$  obtained by adding, for each  $x \in \{0, 1\}$ ,  $m \cdot r \cdot 2^{k^r}$  random copies of  $\Gamma_x$ , then

$$Pr(\Phi \cup \eta \in q\text{-overlap-SAT}(\mathcal{C})) \leq \frac{\tau}{2} \quad (4)$$

**Proof.**

For  $i \in \{1, \dots, r\}$  define  $A_i$  to be the event that the formula  $\Phi$  has a pair of satisfying assignments of overlap  $\simeq q$  with  $X_1 = g_1, \dots, X_i = g_i$ . Also define  $A_0$  to

be the event that  $\Phi \in \text{q-overlap-SAT}(\mathcal{C})$ . The hypothesis translates as the fact that both inequalities  $Pr(A_0) \geq \tau$  and  $Pr(A_r) \leq \frac{\tau}{2}$  are true. Therefore  $Pr(A_r|A_0) = \frac{Pr(A_r \wedge A_0)}{Pr(A_0)} \leq \frac{\tau/2}{\tau} = \frac{1}{2}$ . Since  $\overline{A_{r-1}} \Rightarrow \overline{A_r}$  we have

$$\mu_r := Pr[\overline{A_r}|A_0] = Pr[\overline{A_{r-1}}|A_0] + Pr[\overline{A_r}|A_{r-1} \wedge A_0] \cdot Pr[A_{r-1}|A_0] \geq \frac{1}{2} \quad (5)$$

But  $Pr[\overline{A_r}|A_{r-1} \wedge A_0] = Pr[\overline{A_r}|A_{r-1}]$  is the fraction of variables in formula  $\Phi \wedge (X_1 = g_1) \wedge \dots \wedge (X_{r-1} = g_{r-1})$  that have to receive values different from  $g_r$  in order for the resulting formula to still have two satisfying assignments of overlap  $\sim q$ ; let  $C_r$  be the set of such variables. If instead of the last unit constraint we add a random copy of constraint  $\Gamma_{g_r}$ , the resulting formula is in  $\text{q-overlap-SAT}(\mathcal{C})$  when all the variables appearing in the new constraint are in the set  $C_r$ . Denoting  $\lambda_r = Pr[\overline{A_r}|A_{r-1}]$ , the probability of this last event happening is  $\lambda_r^k / (1 - o(1))$  (we choose a  $k$ -tuple of distinct variables from a set of density  $\lambda_r$ ); Thus the probability that the new formula is in  $\text{q-overlap-SAT}(\mathcal{C})$  is at least  $\nu_r := Pr[A_{r-1}|\overline{A_0}] + \frac{\lambda_r^k}{1 - o(1)} \cdot Pr[\overline{A_{r-1}}|\overline{A_0}]$ . Applying Jensen's inequality to the convex function  $f(x) = x^k$  and using inequality (5), we infer

$$\begin{aligned} \frac{1}{2^k} &\leq \mu_r^k = (Pr[A_{r-1}|\overline{A_0}] \cdot 1 + Pr[A_r|\overline{A_{r-1}}] \cdot Pr[\overline{A_{r-1}}|\overline{A_0}])^k \leq \\ &\leq Pr[A_{r-1}|\overline{A_0}] \cdot 1^k + Pr[A_r|\overline{A_{r-1}}]^k \cdot Pr[\overline{A_{r-1}}|\overline{A_0}] = \\ &= (Pr[A_{r-1}|\overline{A_0}] + \lambda_r^k \cdot Pr[\overline{A_{r-1}}|\overline{A_0}]) = \nu_r \cdot (1 + o(1)). \end{aligned}$$

Thus  $\nu_r \geq \frac{1}{2^k} \cdot (1 - o(1))$ . The conclusion of this long argument is that adding one random copy of  $\Gamma_{b_r}$  instead of the  $r$ -th constraint lowers the probability of membership to  $q$ -overlap-SAT( $\mathcal{C}$ ) to no less than  $\frac{1}{2^k} \cdot (1 - o(1))$ . Adding the copy of the constraint *before* the first  $r - 1$  unit constraints and repeating the argument recursively implies the fact that, if instead of adding the  $r$  unit constraints to  $\Phi$  we add  $r$  random copies of  $\Gamma_{b_1}, \dots, \Gamma_{b_r}$  that the resulting formula belongs to  $q$ -overlap-SAT( $\mathcal{C}$ ), given that  $\Phi \in q$ -overlap-SAT( $\mathcal{C}$ ), is at least  $\gamma_r = \frac{1}{2^{kr}(1 - o(1))}$ . Since the values  $b_1, \dots, b_r$  can repeat themselves, the same is true if we add  $r$  random copies of  $\Gamma_x$  for *every*  $x$ .

Suppose now that we add  $r \cdot m \cdot 2^{k^r}$  copies of each  $\Gamma_x$  (that is, we repeat the random experiment  $m \cdot 2^{k^r}$  times, for some integer  $m \geq 1$ ). The probability that none of the experiments will make the resulting formula unsatisfiable is at most  $(1 - \gamma_r)^{m \cdot 2^{k^r}}$ . For some constant  $m$  this is going to be at most  $1 - \frac{\tau}{2}$ . This means that  $Pr(\Phi \cup \eta \text{ is satisfiable}) \leq \frac{\tau}{2}$ .  $\square$

We can refute condition (4) directly, thus obtaining a contradiction. To do so, we employ the following result (Lemma 3.1 in [AF99]):

**Lemma 3.** *For a monotone property<sup>1</sup>  $A$  let  $\mu(p) = Pr[G \in \Gamma(n, p) \text{ has property } A]$ , and let  $\mu^+(p, M) = Pr[G_1 \cup G_2 \mid G_1 \in \Gamma(n, p), G_2 \in \Gamma(n, M) \text{ has property } A]$ .*

*Let  $A = A(n) \subseteq \{0, 1\}^n$  be a monotone property and  $M = M(n)$  such that  $M = o(\sqrt{np})$ . Then  $|\mu(p) - \mu^+(p, M)| = o(1)$ .*

<sup>1</sup> Achlioptas and Friedgut assume  $A$  to be a monotone *graph* property, but this fact is not used anywhere in their proof.

We obtain a contradiction in the following way: consider a random formula  $\eta$  with  $f(n)$  clauses, for some  $f(n) \rightarrow \infty$ . It is easy to show that the probability that  $\eta$  contains, for some  $x$ , less than  $r \cdot m \cdot 2^{k^r}$  copies of  $\Gamma_x$  (with  $r, m$  as in Lemma 2) is  $o(1)$ . So adding  $\eta$  (instead of the random formula in Lemma 2) decreases the probability of  $q$ -satisfiability by at least  $\delta - o(1)$ . But this contradicts the conclusion of Lemma 3.  $\square$

## 5 Proof of Theorem 2

We will use the well-known graph-theoretic interpretation of 2-CNF formulas, that associates to a given formula  $\Phi$  on  $n$  variables a directed graph  $G_\Phi$  with  $2n$  vertices  $\{x_1, \dots, x_n, \bar{x}_1, \dots, \bar{x}_n\}$ , and for every clause  $C = \alpha \vee \beta$  of  $\Phi$  it adds directed edges  $\bar{\alpha} \rightarrow \beta$  and  $\bar{\beta} \rightarrow \alpha$  to  $G_\Phi$ . We will need a number of results from [RPF99] concerning the structure of graph  $G_\Phi$  when  $\Phi$  is a random formula of constraint density  $c < 1$ .

**Definition 7.** A cycle is a set  $l_1 \rightarrow l_2, l_2 \rightarrow l_3, \dots, l_s \rightarrow l_1$  of directed edges. Two cycles  $C_1, C_2$  are overlapping if they share at least an edge. Two cycles  $C_1, C_2$  are connected by a path if there exist vertices  $x \in C_1, y \in C_2$  and a path (possibly of length zero, i.e.  $x = y$ ) from  $x$  to  $y$ .

**Lemma 4.** Let  $t = t(n)$  such that  $1 = o(t)$ . Let  $\Phi$  be a random 2-CNF formula of constraint density  $c < 1$  and  $G_\Phi$  be its associated digraph. With probability  $1 - o(1)$  the following are true: (i)  $G_\Phi$  contains no cycles connected by a path. (ii)  $G_\Phi$  contains no overlapping cycles. (iii) the sum of all the cycle lengths is less than  $t$ .

To these results we add the following claim (whose proof is similar to that of Claim 4 (i) from [RPF99]): With probability  $1 - o(1)$  no literal implies literals in two different cycles.

We can thus divide the literals of the formula into four classes: (i) those that are on a cycle. (ii) those that are not on a cycle, but *imply* a literal on a cycle. (iii) those that are not on a cycle, but are *implied* by a literal on a cycle. (iv) those that are not on a cycle and neither imply nor are implied by a literal on a cycle.

**Definition 8.** A literal  $x$  is bad if there exists  $y$  such that  $x \xrightarrow{*} y, x \xrightarrow{*} \bar{y}$ .

We first claim that there is a function  $h(n) = o(n)$  such that with probability  $1 - o(1)$  the number of bad literals is at most  $h(n)$ . Indeed, all bad literals can only be set to false in any satisfying assignment of the formula. This means that a bad literal belongs to the *spine* of the formula [BBC<sup>+</sup>01]. But a standard argument (see e.g. [IPB05]) shows that the size of the spine is  $o(n)$ .

Bad literals (and their negations) are assigned fixed values in all satisfying assignments. This property guarantees that such literals do not influence the value of the overlap between any two satisfying assignments. Let  $\mathcal{B}$  be the set of such literals.

**Theorem 2(i):** Let  $A$  and  $B$  be two satisfying assignments of a formula  $\Phi$ , such that  $d(A, B) > \log n$  (i.e.  $A$  and  $B$  are not adjacent). We will prove the following result:

**Lemma 5.** There exists a satisfying assignment  $C$  such that  $d(A, C) = O(\log n)$  and  $d(C, B) < d(A, B)$ . That is,  $C$  is adjacent to  $A$  and closer to  $B$  than  $A$ .

An iterative application of the lemma proves the Theorem 2(i).

**Proof:** Let  $x$  be a variable such that  $A(x) \neq B(x)$  and  $x$  is *implication minimal* with this property. In other words if  $y \neq x$  and  $y \xrightarrow{*} x$  then  $A(y) = B(y)$ .

**Case 1:**  $A(x) = 0$  and  $B(x) = 1$ . Then  $B(z) = 1$  for all  $z$  such that  $x \xrightarrow{*} z$ . Define the assignment  $C$  by  $C(z) = 1$  if  $x \xrightarrow{*} z$ ,  $C(z) = A(z)$  otherwise. It is clear that  $d(C, B) < d(A, B)$ , since  $C$  coincides with  $B$  on all bits whose value changes. To show that  $C$  is a satisfying assignment, suppose  $C$  did not satisfy some clause  $W = (\alpha \vee \beta)$ . Then one of the following is true.

- (1): both  $\alpha$  and  $\beta$  are negations of literals implied by  $x$ . This leads to a contradiction, since it would imply that  $B$  does not satisfy clause  $\alpha \vee \beta$  either.
- (2): one of them (say  $\alpha$ ) is the negation of a literal implied by  $x$ . Since  $x \xrightarrow{*} \bar{\alpha}$  and  $\bar{\alpha} \rightarrow \beta$ , it follows that  $C(\beta) = 1$ , so  $C$  satisfies clause  $W$ .
- (3): none of them is the negation of a literal implied by  $x$ . Then  $C(\alpha) = A(\alpha)$  and  $C(\beta) = A(\beta)$ , a contradiction, since  $A$  satisfies clause  $W$ .

**Case 2:**  $A(x) = 1$  and  $B(x) = 0$ . Then  $B(z) = 0$  for all  $z$  such that  $z \xrightarrow{*} x$ . Define the assignment  $C$  by  $C(z) = 0$  if  $z \xrightarrow{*} x$ ,  $C(z) = A(z)$  otherwise. It is clear that  $d(C, B) < d(A, B)$ , since  $C$  coincides with  $B$  on all the bits that change value, one of which is  $x$ . To show that  $C$  is a satisfying assignment, suppose  $C$  did not satisfy some clause  $\alpha \vee \beta$ . Then one of the following cases must hold

- (1): both  $\alpha$  and  $\beta$  are literals that imply  $x$ . This leads to a contradiction, since this would mean that  $B$  with respect to satisfying clause  $\alpha \vee \beta$ .
- (2): one of them (say  $\alpha$ ) implies  $x$ . Since  $\bar{\beta} \xrightarrow{*} \alpha$ , it follows that  $\bar{\beta} \xrightarrow{*} x$ , therefore  $\beta$  is assigned the value TRUE by  $C$ , a contradiction.
- (3): none of  $\alpha, \beta$  implies  $x$ . Then  $C$  and  $A$  coincide with respect to the values they give to  $\alpha, \beta$ , a contradiction, since  $A$  satisfies clause  $W$ .

**Theorem 2(ii):** We directly construct two satisfying assignments  $A$  and  $B$  of overlap  $qn \pm \sqrt{n}$ . We will work with a directed weighted graph  $G_2$  obtained from  $G_\Phi$  by contracting every cycle to a node and assigning this node a weight equal to twice the size of the contracted cycle.  $G_2$  is well-defined when cycles in  $G_\Phi$  do not intersect, an event that happens (cf. Claim 4) with probability  $1 - o(1)$ . All literals on a cycle of  $G_\Phi$  need, of course, to be given the same value in any satisfying assignment. Since we have contracted all cycles in  $G_\Phi$ ,  $G_2$  is a directed acyclic graph. The set of nodes corresponding to bad literals is downward closed, because if  $x \rightarrow y$  and  $y$  is bad then  $x$  is bad. Correspondingly, the set of nodes corresponding to negations of a bad literal is upward closed.

We begin by defining a set  $S$  of nodes of  $G_2$  that will ultimately contain half of the nodes in  $G_2$ . Nodes not chosen in  $S$  will be referred to as *eliminated*. In parallel we build a partial assignment by assigning those literals corresponding to eliminated nodes the unique values that are consistent with the satisfiability of the formula. Set  $S$  is recursively specified as follows: (i) start by defining  $V$  to be the set of all nodes in  $G_2$  (ii) add all nodes of of indegree 0 in  $V$  to  $S$  and eliminate all nodes of outdegree 0. Set  $V$  to be the set of remaining nodes (not added to  $S$  or eliminated). (ii) continue this process as long as  $V \neq \emptyset$ .

It is easy to see that the set of literals corresponding to nodes in  $S$  contains, for every variable  $x$ , exactly one of  $x$  and  $\bar{x}$ . Indeed, one cannot add both  $x$  and  $\bar{x}$  to  $S$  in one step, otherwise the pure literal implying both would be bad. But then, when adding one of them we immediately eliminate the other one. On the other hand, we only eliminate a literal when its opposite has been retained in  $S$ .

The first assignment,  $A$  simply corresponds to setting all literals corresponding to nodes in  $S$  to TRUE. We define the second assignment iteratively by the following process: (i) in Stage 1 choose a node of indegree zero, assign its associated variable the value FALSE and eliminate the node from  $S$ . If the eliminated node corresponds to a cycle in  $G_2$  all variables in the cycle are set to FALSE. (ii) when a remaining node becomes of indegree zero as a result of eliminations, it is labeled by the value of the stage that led to this happening (nodes that originally had indegree zero are labelled 0). (iii) the literal chosen to set to FALSE is among those with a smallest stage number. (iv) continue the process until the number of variables assigned FALSE is in the interval  $[qn - \sqrt{n}, qn + \sqrt{n}]$ . This is possible if the sum of all cycle lengths in the formula graph of  $\Phi$  is  $o(\sqrt{n})$ , which happens (cf. Lemma 4) with probability  $1 - o(1)$ . (v) The remaining literals in  $S$  are set to TRUE.

Because bad literals are assigned identical values in both  $A$  and  $B$  it is easy to see that  $overlap(A, B) \in [qn - \sqrt{n}, qn + \sqrt{n}]$ . We complete the proof of Theorem 2 by:

**Lemma 6.**  *$A$  and  $B$  are satisfying assignments for  $\Phi$ .*

**Proof:** Suppose there exists a clause  $C = (\bar{x} \vee y) \equiv (x \rightarrow y)$  of  $\Phi$  that is not satisfied by  $A$ . Then  $x$  is given a TRUE value and  $y$  is given a FALSE value. Thus either  $\bar{x}$  is a bad literal, or  $x$  is in  $S$ . Also, either  $y$  is a bad literal or  $\bar{y}$  is in  $S$ . Suppose  $y$  were a bad literal. Then, since  $x \rightarrow y$ ,  $x$  is also bad. But this contradicts the two possible alternatives ( $\bar{x}$  is a bad literal or  $x$  is in  $S$ ). Suppose now  $\bar{y}$  is in  $S$ . Then  $C \equiv (\bar{y} \rightarrow \bar{x})$ . Therefore, either  $\bar{x} \in S$  or  $\bar{x}$  is among the literals (bad literals and their negations) eliminated before defining  $S$ . The first alternative leads to a contradiction with the two possible alternatives ( $\bar{x}$  is a bad literal or  $x$  is in  $S$ ), so it must be that  $\bar{x}$  is a bad literal. But then  $\bar{y}$  is also bad, contradicting the assumption that  $\bar{y}$  is in  $S$ .

A similar argument shows that  $B$  is a satisfying assignment. Indeed, suppose there existed a clause  $C = (\bar{x} \vee y) \equiv (x \rightarrow y)$  of  $\Phi$  not satisfied by  $B$ . Then  $B(x) = TRUE$ ,  $B(y) = FALSE$ . The choices compatible with this setup are: (i)  $x$  is in  $S$  and  $B(x) = TRUE$ , or  $\bar{x}$  is bad. (ii)  $y$  is bad, or  $y$  is in  $S$  and  $B(y) = FALSE$ , or  $\bar{y} \in S$  and  $B(\bar{y}) = TRUE$ , i.e.  $B(y) = FALSE$ . First, if  $y$  were bad then so would be  $x$ , contradicting all possible choices in (i). If  $x, y$  were both in  $S$ , with  $y$  assigned FALSE, since by construction of  $B$  the set of literals in  $S$  is downward closed under implication it follows that  $x$  would also be assigned FALSE, a contradiction. The other possibility is that  $\bar{x}$  is bad. But since  $\bar{y} \rightarrow \bar{x}$  that would mean that  $\bar{y}$  is bad, a contradiction with the assumption that  $y \in S$ . Finally, assume  $\bar{y}$  is in  $S$  and is assigned TRUE. Since  $\bar{y} \rightarrow \bar{x}$  either  $\bar{x} \in S$  or  $x$  is a bad literal. In the first case, since the set of literals assigned to TRUE is upward closed under implication it would mean that  $\bar{x}$  is assigned TRUE by  $B$ , i.e.  $x$  is assigned FALSE, a contradiction. Suppose now that  $x$  is bad. Then  $B(x) = 0$ , a contradiction.  $\square$
